Abstract
Crohn's disease is a type of chronic inflammatory bowel disease (IBD) of unknown etiology that may affect any part of the gastrointestinal tract from mouth to anus [1,2]. It typically presents as a recurrent course of patchy transmural inflammation with normal intestinal mucosa in between the diseased part followed by relapses [3,4]. It also manifests with extra-intestinal complications most common being arthralgia/arthritis, and cutaneous, ophthalmologic and hepatobilary manifestations. Smoking is considered as an important risk factor [5]. The treatment of this incurable disease aims at reducing the disease process, decreasing the number of relapses and improving the quality of life [6].

This case report describes a 40 years old Moroccan female known to have documented evidence of significant Crohn’s disease since past 10 years. She is diagnosed with multiple fistulas that are a rare entity of patients with Crohn’s disease, which is itself a rare disease in African countries.

Introduction
Crohn's disease is a type of chronic inflammatory bowel disease (IBD) of unknown etiology that may affect any part of the gastrointestinal tract from mouth to anus [1,2]. It typically presents as a recurrent course of patchy transmural inflammation with normal intestinal mucosa in between the diseased part followed by relapses [3,4]. It also manifests with extra-intestinal complications most common being arthralgia/arthritis, and cutaneous, ophthalmologic and hepatobilary manifestations. Smoking is considered as an important risk factor [5]. The treatment of this incurable disease aims at reducing the disease process, decreasing the number of relapses and improving the quality of life [6].

This case report describes a 40 years old Moroccan female known to have documented evidence of significant Crohn’s disease since past 10 years. She is diagnosed with multiple fistulas that are a rare entity of patients with Crohn’s disease, which is itself a rare disease in African countries.
Case presentation

A 40 years old Moroccan female with a past history of significant Crohn’s disease since last 10 years presented to emergency room with severe gluteal and abdominal pain as well as a febrile condition (Figure 1). She denied the presence of chills, nausea and vomiting in her presenting complains and stated that she had normal bowel movements over the past one week.

The patient stated that she had occasional nausea and vomiting, crampy abdominal pain with bloating associated with meal intake and occasional diarrhea in the last 10 years leading to significant weight loss of 15 pounds over the previous 1–2 months. She denied any extra intestinal manifestations of her disease.

She was medically managed on infliximab for approximately 5 years but switched later to cetolizumab due to episodes of exaggerations between the doses. The next drug also failed after 1–2 months as she started having acute exaggerative episodes in the last few months. She had pre-operative colonoscopy, a year ago, after which she was recommended exploratory laparotomy with possible resection of diseased bowel but she denied it due to financial reasons.

Of all her past record of IV with oral contrast CT scans, the latest one that was performed approximately a year ago stated that the patient had moderately distended small bowel, compatible with small bowel obstruction, due to significant inflammatory edematous thickening of the terminal ileum. There was also evidence of multiple enterenteric fistulas. In addition, there was an inflamed small bowel loop inseparable from the superior wall of bladder with presence of gas in the urinary bladder demonstrating evidence of enterovesicular fistula.

She also had colonoscopy a year ago that showed classical features of chronic inflammatory disease with tuberculosis in the sigmoid and the cecum except that there were no ulcerations present. The distal transverse colon and the entire descending colon appeared to be free of obvious disease. Overall pattern suggested of skip lesions with anal involvement classical for Crohn’s disease.

The patient was operated with exploratory laparotomy discovering a fistula between sigmoid and cecum as well as a fistula between cecum and the right wall. We first did a fistulotomy of the fistula between the sigmoid and the cecum, then we proceeded to an ileocecal resection with ileocolic anastomosis then we tried a resection of 4 apparent fistulas tracks in the gluteal region (Figure 2, 3). Informed consent was taken from patient.

Discussion

The gluteal fistula and abscesses have been reported as complications of Crohn’s disease, diverticulitis, colon carcinoma, and tuberculosis of lumbar vertebrae [7,8]. In our patient, recurrent abscesses history in gluteus suggested the possibility that there had been a fistula. In the case presented, initial diagnosis of a fistula could not be made till the visualization of fistulas. Computed tomography is helpful if exact spatial delineation of the tract is necessary or a suspect of associated abscess exists. Because CT results in high radiation, it should be used carefully in young children in selected indications. Ultrasound examination is generally not useful since it is limited by bowel gas and surgical incisions [9,10]. Magnetic resonance imaging (MRI) is reported as the golden standard in preoperative assessing and classifying of fistula, because MRI allows direct visualization of the tracts and abscesses through to high soft tissue resolution [11,12].

Surgery has been the main therapy for any sinus and fistula tracts. Open surgical exploration and repair provide definitive management, avoid recurrence, and prevent infection. Although surgical excision has been considered as a mode of treatment by most of the surgeons, the patient may be faced with some conditions such as nerve injuries, prolonged lymphatic drainage from the wound, recurrent lesions, wound infections, and unacceptable scar formations. Sclerotherapy using bleomycin is an established technique for the treatment of developmental vascular anomalies, also those which are at risk of developing intraoperative damage to vital organs and nerves, and lymphangiomas. Now sclerotherapy has been successfully used in the treatment of congenital sinus tracts [13,14].

Bleomycin is an antitumor agent and, besides its antineoplastic effect, bleomycin causes nonspecific inflammatory reaction leading to fibrosis in the surrounding tissues [15].

Conclusion

The present case is a description of a novel fistula tractus. To the best of our knowledge, this is the first case with
fistula deeply located and extending from the gluteus in the literature. Clinicians should consider underlying congenital malformation in the differential diagnosis of recurrent perineal and/or gluteal abscess. Catheter-based bleomycin injection could be applied as a safe, minimally invasive, and effective option for complex gluteal fistula, which makes it a suitable and durable alternative to open surgery. Treatment of this entity is individualized according to the site of fistula and associated anomalies.
